Code

```
1  #include <iostream>
2  using namespace std;
3
4  class Base {
5  private:
6      int base_private;
7
8  public:
9      Base() {
10         base_private = 1;
11     }
12
13     void PrintBase() {
14         cout << "Base private number: " << base_private << endl;
15     }
16 };
17
18 class Derived : public Base {
19 private:
20     int derived_private;
21
22 public:
23     Derived() {
24         derived_private = 4;
25     }
26
27     void PrintDerived() {
28         cout << "Derived private number: " << derived_private << endl;
29     }
30 };
31
32 int main() {
33     Derived derived;
34
35     derived.PrintBase();
36     derived.PrintDerived();
37
38     return 0;
39 }
```

This program demonstrates inheritance in C++ where a Derived class inherits from a Base class. The Base class contains a private integer initialized to 1 and a function to print it. The Derived class contains its own private integer initialized to 4 and a function to display it. When an object of the derived class is created, both constructors run and the program prints values from both the base and derived parts of the object using their respective functions.

output:

```
Base private number: 1
Derived private number: 4

-----
Process exited after 0.2838 seconds with return value 0
Press any key to continue . . .
```

The output shows two values because the object has both a Base part and a Derived part. First, the Base constructor sets `base_private` to 1, then the Derived constructor sets `derived_private` to 4. So when you call `PrintBase()`, it prints 1, and when you call `PrintDerived()`, it prints 4.

```
1  #include <iostream>
2  using namespace std;
3
4  class Base {
5  private:
6      int base_private;
7
8  protected:
9      int base_protected;
10
11  public:
12      int base_public;
13
14      void setBaseNum(int n1, int n2, int n3) {
15          base_private = n1;
16          base_protected = n2;
17          base_public = n3;
18      }
19
20      void printBase() {
21          cout << base_private << " " << base_protected << " " << base_public << endl;
22      }
23  };
24
25  class Derived : public Base {
26  public:
27      void setBaseNum(int n1, int n2, int n3) {
28          base_protected = n2;
29          base_public = n3;
30      }
31  };
32
33  int main() {
34      Base base;
35      base.setBaseNum(1, 2, 3);
36      base.printBase();
37
38      return 0;
```

This program shows access control in inheritance. The Base class has private, protected, and public variables. Private data can only be used inside the Base class, protected data can be used in the Base and Derived classes, and public data can be accessed anywhere. The Derived class can modify only the protected and public members of the Base class, not the private one. The program sets values using a function and prints them from the Base class.

OUTPUT

```
1 2 3
-----
Process exited after 0.2948 seconds with return value 0
Press any key to continue . . .
```

The program prints the three values stored in the Base object after they are set. The private value is 1, the protected value is 2, and the public value is 3.

Code

```
1  #include <iostream>
2  using namespace std;
3
4  class Base {
5  private:
6      int base_num;
7
8  public:
9      Base() {
10         base_num = 1;
11         cout << "Constructor of base class" << endl;
12     }
13
14     Base(int n1) {
15         base_num = n1;
16         cout << "Constructor of base class" << endl;
17     }
18 };
19
20 class Derived : public Base {
21 private:
22     int derived_num;
23
24 public:
25     Derived(int n) {
26         derived_num = n;
27         cout << "Constructor of derived class" << endl;
28     }
29
30     Derived(int n1, int n2) : Base(n1) {
31         derived_num = n2;
32         cout << "Constructor of derived class" << endl;
33     }
34 };
35
36 int main() {
37     Derived* ptr1 = new Derived(2);
38     Derived* ptr2 = new Derived(1, 2);
```

This program demonstrates constructors in inheritance. The Base class has two constructors, one default and one parameterized. The Derived class also has two constructors. When a Derived object is created, the Base constructor is called first before the Derived constructor. In the second constructor, the Base constructor is explicitly called using : Base(n1).

OUTPUT

```
Constructor of base class
Constructor of derived class
Constructor of base class
Constructor of derived class

-----
Process exited after 0.2935 seconds with return value 0
Press any key to continue . . .
```

For Derived(2), the Base default constructor runs first, then the Derived constructor runs.

For Derived(1,2), the Base parameterized constructor runs first, then the Derived constructor runs.

CODE

```
1  #include <iostream>
2  using namespace std;
3
4  class Base {
5  public:
6      Base() {
7          cout << "Constructor of base class" << endl;
8      }
9
10     ~Base() {
11         cout << "Destructor of base class" << endl;
12     }
13 };
14
15 class Derived : public Base {
16 public:
17     Derived() {
18         cout << "Constructor of derived class" << endl;
19     }
20
21     ~Derived() {
22         cout << "Destructor of derived class" << endl;
23     }
24 };
25
26 int main() {
27     Derived *ptr1 = new Derived();
28
29     delete ptr1;
30
31     return 0;
32 }
```

This program shows constructors and destructors in inheritance. When a Derived object is created using new, first the Base constructor runs, then the Derived constructor. When the object is deleted using delete, the destructors run in reverse order: first Derived destructor, then Base destructor.

OUTPUT

C:\Users\Kamwai\Desktop\ED\Year 2\OOP\NS\Destructor of derived class.exe

```
Constructor of base class
Constructor of derived class
Destructor of derived class
Destructor of base class

-----
Process exited after 0.2988 seconds with return value 0
Press any key to continue . . .
```

When the object is created, Base constructor runs first, then Derived constructor. When it is deleted, Derived destructor runs first, then Base destructor.

CODE

```
1  #include <iostream>
2  #include <cstring>
3  using namespace std;
4
5  class Person {
6  private:
7      char *name;
8      int age;
9
10 public:
11     Person(int age, const char *name) {
12         this->age = age;
13
14         this->name = new char[strlen(name) + 1];
15         strcpy(this->name, name);
16     }
17
18     ~Person() {
19         delete[] name;
20     }
21
22     void PrintPerson() {
23         cout << "My age is " << age << endl;
24         cout << "My name is " << name << endl;
25     }
26 };
27
28 class Student : public Person {
29 private:
30     char *major;
31
32 public:
33     Student(int age, const char *name, const char *major)
34         : Person(age, name) {
35
36         this->major = new char[strlen(major) + 1];
37         strcpy(this->major, major);
38     }
39
40     void PrintStudent() {
41         PrintPerson();
42         cout << "My major is " << major << endl;
43     }
44 };
45
46
47
48
49
50 int main() {
51     Student s(20, "John", "Computer Science");
52
53     s.PrintStudent();
54
55     return 0;
56 }
```

This program demonstrates dynamic memory allocation and inheritance. The Person class stores a name and age using dynamically allocated memory, and the Student class inherits from Person while adding a major field, also stored dynamically. Constructors allocate memory, and destructors free it to prevent memory leaks. The student object prints all its information using both parent and child class functions.

OUTPUT

```
My age is 20
My name is John
My major is Computer Science

-----
Process exited after 0.2783 seconds with return value 0
Press any key to continue . . .
```

The program prints the person's age and name first (from the base class), then prints the student's major (from the derived class)

Multiple inheritance code

```

1  #include <iostream>
2  using namespace std;
3
4  class Mid1 {
5  private:
6      int number;
7
8  public:
9      Mid1(int num) {
10         number = num;
11     }
12
13     void Mid1_function() {
14         cout << "Mid1 number is " << number << endl;
15     }
16 };
17
18 class Mid2 {
19 private:
20     int number;
21
22 public:
23     Mid2(int num) {
24         number = num;
25     }
26
27     void Mid2_function() {
28         cout << "Mid2 number is " << number << endl;
29     }
30 };
31
32 class Final : public Mid1, public Mid2 {
33 public:
34     Final(int num1, int num2)
35         : Mid1(num1), Mid2(num2) {}
36 };
37
38 int main() {
39     Final f(1, 2);
40
41     f.Mid1_function();
42     f.Mid2_function();
43
44     return 0;
45 }

```

This program demonstrates multiple inheritance in C++. The class Final inherits from both Mid1 and Mid2. Each parent class stores its own integer value. The Final constructor passes values to both base classes using an initialization list. The program then calls functions from both base classes to display their stored values.

OUTPUT

```

Mid1 number is 1
Mid2 number is 2

-----
Process exited after 0.432 seconds with return value 0
Press any key to continue . . .

```

The object Final f(1, 2) stores 1 in Mid1 and 2 in Mid2. When the functions are called, each class prints its own value

Ambiguity of Multiple inheritance

```

1  #include <iostream>
2  using namespace std;
3
4  class Mid1 {
5  private:
6      int number;
7
8  public:
9      Mid1(int num) {
10         number = num;
11     }
12
13     void Mid1_function() {
14         cout << "Mid1 number is " << number << endl;
15     }
16 };
17
18 class Mid2 {
19 private:
20     int number;
21
22 public:
23     Mid2(int num) {
24         number = num;
25     }
26
27     void Mid2_function() {
28         cout << "Mid2 number is " << number << endl;
29     }
30 };
31
32 class Final : public Mid1, public Mid2 {
33 public:
34     Final(int num1, int num2)
35         : Mid1(num1), Mid2(num2) {}
36 };
37
38 int main() {
39     Final f(1, 2);
40
41     f.Mid1_function();
42     f.Mid2_function();
43
44     return 0;
45 }

```

This program demonstrates multiple inheritance in C++ where the class Final inherits from both Mid1 and Mid2. Each parent class stores its own integer value and has a function to print it. The Final class constructor passes values to both base classes using an initialization list.

OUTPUT

```
Mid1 number is 1
Mid2 number is 2

-----
Process exited after 0.3631 seconds with return value 0
Press any key to continue . . .
```

The object Final f(1, 2) creates two separate values, one for each parent class. When the functions are called, each class prints its own stored number.

Code 2

```
1  #include <iostream>
2  using namespace std;
3
4  class Base {
5  private:
6      int number;
7
8  public:
9      Base(int num) {
10         number = num;
11     }
12
13     void Base_function() {
14         cout << "Base number is " << number << endl;
15     }
16 };
17
18 class Mid1 : public Base {
19 public:
20     Mid1(int num) : Base(num) {}
21 };
22
23 class Mid2 : public Base {
24 public:
25     Mid2(int num) : Base(num) {}
26 };
27
28 class Final : public Mid1, public Mid2 {
29 public:
30     Final(int num1, int num2)
31         : Mid1(num1), Mid2(num2) {}
32 };
33
34 int main() {
35     Final f(1, 2);
36 }
```

```

37     f.Mid1::Base_function();
38     f.Mid2::Base_function();
39
40     return 0;
41 }

```

This program demonstrates multiple inheritance with a shared base class (diamond structure without virtual inheritance). The class `Base` stores a number and prints it. `Mid1` and `Mid2` both inherit from `Base`, and `Final` inherits from both of them. Because of this structure, `Final` contains two separate copies of `Base`, one from each parent class.

OUTPUT

```

Base number is 1
Base number is 2
-----
Process exited after 0.4366 seconds with return value 0
Press any key to continue . . .

```

The object `Final f(1, 2)` creates two separate `Base` objects: one through `Mid1` and one through `Mid2`. When the functions are called, each path prints its own stored value.

VIRTUAL INHRITANCE CODE

```

1  #include <iostream>
2  using namespace std;
3
4  class Base {
5  private:
6      int number;
7
8  public:
9      Base(int num) {
10         number = num;
11     }
12
13     void Base_function() {
14         cout << "Base number is " << number << endl;
15     }
16 };
17
18 class Mid1 : virtual public Base {
19 public:
20     Mid1(int num) : Base(num) {}
21 };
22
23 class Mid2 : virtual public Base {
24 public:
25     Mid2(int num) : Base(num) {}
26 };
27
28 class Final : public Mid1, public Mid2 {
29 public:
30     Final(int num) : Base(num), Mid1(num), Mid2(num) {}
31 };
32
33 int main() {
34     Final f(1);
35
36     f.Base_function();

```

This program demonstrates virtual inheritance in C++. The Base class contains a number and a function to print it. Both Mid1 and Mid2 inherit from Base using virtual inheritance, which ensures that only one shared copy of Base exists inside Final. The Final class initializes the Base constructor directly to avoid duplication issues.

```

Base number is 1
-----
Process exited after 0.3681 seconds with return value 0
Press any key to continue . . .

```

Because virtual inheritance ensures only one Base exists inside Final, the value is set once and shared. So when Base_function() is called, it prints.
